57 Abstract

58 **Objective:** Examine the association between preeclampsia and attention deficit hyperactivity
59 disorder (ADHD), using a large Swedish-based registry cohort.

60 **Methods:** This study comprised 2,047,619 children, with 114,934 (5.6%) cases of ADHD.
61 Preeclampsia was based on two alternate definitions: 1.Preeclampsia (using ICD-9/ICD-10)

2. Preeclampsia and small for gestational age (SGA) combined. ADHD was determined in one of two ways: 1. If a diagnosis of ADHD was present in the National Patient Register or 2. If an individual was in receipt of ADHD medication in the Prescribed Drug Register. Multivariate Cox proportional hazards regression analysis allowed adjustment for several perinatal/sociodemographic factors. Sibling-matched analysis further controlled for shared genetic and familial confounding.

Results: In the adjusted Cox model, preeclampsia was associated with an increase in likelihood of ADHD (HR: 1.15, 95% CI: 1.12, 1.19). The HR for preeclampsia and those born SGA was 1.43 (95% CI: 1.31, 1.55) in the adjusted model, compared to those unexposed to preeclampsia/SGA. The sibling-matched analysis did not materially change these associations (HR: 1.13, 95% CI: 1.05, 1.22) and 1.55 (95% CI: 1.28, 1.88).

Conclusions: Exposure to preeclampsia or preeclampsia/SGA was associated with ADHD, independent of genetic/familial factors shared by siblings. However, it is important to note that sibling-matched analysis can only adjust for factors that are constant between pregnancies, therefore residual confounding cannot be ruled out. Further research is needed to explore modifiable risk factors and identify those most-at-risk babies following delivery.

Keywords: Preeclampsia, Obstetric complications, Attention Deficit Hyperactivity Disorder, Epidemiology.

Significant Outcomes

- This population-based cohort study suggests that preeclampsia, as well as preeclampsia and small for gestational age (SGA) combined (i.e. SGA baby exposed to preeclampsia), are associated with an increase in the likelihood of ADHD, independent of genetic/familial factors shared by siblings.
- Placental pathology may be a common mechanism increasing the likelihood of ADHD as a stronger association was observed for preeclampsia/SGA, rather than preeclampsia alone.
- Further research is needed to explore modifiable risk factors and identify those most-at-risk babies following delivery.

Limitations

- A lack of robust data on gestational hypertension limited the analysis to preeclampsia-ADHD only; therefore, the comparison group may contain women with a diagnosis of gestational hypertension. However, a gestational hypertension-ADHD association would more likely bias our results towards the null.
- Outpatient data only started becoming available in 2001, meaning more severe cases of ADHD may have been overrepresented due to a reliance on inpatient data. However, restricting the study population to 2001-2010 did not have a large impact on findings.
- While sibling-matched analysis may have reduced confounding due to shared genetic and familial factors, the possibility of residual confounding cannot be ruled out in observational studies.

Introduction

Preeclampsia, which affects approximately 5% of all pregnancies¹, is one of the leading causes of maternal morbidity and mortality, and was recently redefined by the International Society for the Study of Hypertension in Pregnancy (ISSHP) as gestational hypertension accompanied by at least two of the following: proteinuria and/or other maternal organ dysfunction and/or uteroplacental dysfunction².

Attention deficit hyperactivity disorder (ADHD) is a neurodevelopmental disorder characterised by inattention, hyperactivity and impulsivity. ADHD has a global pooled prevalence of over 5%, and while this estimate varies significantly worldwide, the variability can mostly be explained by methodological differences between studies^{3, 4}. Despite high heritability estimates, gene environment interactions may also play a role⁵.

Preeclampsia has been linked to adverse neurodevelopmental outcomes, including ADHD^{6, 7}. Pooled results from a recent systematic review suggest that preeclampsia is associated with a 30% increase in odds of ADHD⁶. It is worth noting however, that while an apparent relationship exists in previous literature, residual confounding and quality of the studies may be a concern. For example, only one of ten studies included in the systematic review controlled for a combination of key potential confounders, such as maternal age, socioeconomic status, ethnicity, and maternal mental illness^{6, 8}.

Aim of the study

125 The aim of this study was to examine the association between preeclampsia and ADHD using a
126 large population-based cohort study, controlling for a wide range of potential confounding factors,
127 as well as shared genetic and familial confounding through sibling-matched analysis.

128

129

130

131 **Materials and Methods**

132 **Study Population**

133 All singleton live births in Sweden from 1990 to 2010, with a follow-up until December 2016,
134 were included in the study. Data were obtained from Swedish National Registers. These included
135 the Medical Birth Register, National Patient Register, Prescribed Drug Register, Multi-generation
136 Register, Total Population Register and Register of Education, linked using personal identification
137 numbers assigned to Swedish residents⁹.

138 Ethical approval was previously obtained from the Stockholm Regional Ethical Review Board
139 (number 2010/1185-31/5), and informed consent was waived by the ethics committee.

140

141 **Exposures**

142 **Preeclampsia**

143 Data on preeclampsia was obtained from the Medical Birth Register which contains data on over
144 97% of all births in Sweden¹⁰. We used two alternate definitions of preeclampsia:

145 1. *Preeclampsia*: Blood pressure $\geq 140/90$ mmHg on or after 20 weeks' gestation combined with
146 proteinuria (≥ 0.3 g/day or ≥ 1 on a urine dipstick on at least two occasions). Preeclampsia was
147 classified using the Swedish version of the ICD, Ninth and Tenth Revision¹¹: ICD-9 until 1996
148 (codes 642E-G) and ICD-10 from 1997 (codes O14-O15)^{12, 13}.

149 2. *Preeclampsia and small for gestational age (SGA) combined*: We combined preeclampsia (as
150 above) and SGA as a proxy for preeclampsia with placental dysfunction². SGA was defined as
151 birthweight < 2 standard deviations below the mean of the sex-specific and gestational age
152 distributions¹⁴.

153

154

155

156 **Outcome**

157 Data on ADHD were obtained from the National Patient Register and the Prescribed Drug
158 Register. The National Patient Register was launched in 1964, contains inpatient psychiatric
159 diagnoses from 1973, and outpatient data since 2001 (with increasingly better coverage until
160 2006)¹⁵⁻¹⁷. The Prescribed Drug Register was expanded on 1st July 2005 to include personal
161 identification numbers allowing linkage to other registers^{17, 18}.

162 A diagnosis of ADHD was determined in one of two ways:

163 1. If a diagnosis of ADHD was present in the National Patient Register, using ICD-10 (code F90
164 and F98.8), available since 1997¹⁷.

165 2. If the subject was in receipt of ADHD medication in the Prescribed Drug Register. ADHD
166 medication data was classified according to Anatomical Therapeutic Chemical classification
167 system, and included amphetamine (N06BA01), dexamphetamine (N06BA02), psychostimulants
168 methyphenidate (N06BA04) and noradrenergic reuptake inhibitor atomoxetine (N06BA09).

170 **Confounding Factors**

171 Potential confounders were based on previous literature. Year of birth, infant sex, maternal age,
172 parental country of birth, parity, maternal smoking status, body mass index (BMI) at first antenatal
173 visit and gestational weight gain were obtained from the Medical Birth Register. Parental
174 depression, bipolar disorder, and non-affective psychiatric disorders were obtained from the
175 National Patient Register. Family income and parental level of education data were obtained from
176 the Total Population Register and Register of Education. Information on all cofounders was
177 available for the entire study period. Where a variable had missing data, the data were added as a
178 separate category and included in the various Cox regression analyses by means of an indicator
179 variable to ensure that all cases were included in the analyses¹⁹. (See eMethods for description of
180 confounders).

182 **Statistical Analysis**

183 All data were analysed using Stata/MP 14.2. We conducted Cox proportional hazards regression
184 analysis to calculate a hazard ratio (HR) and 95% confidence interval for a preeclampsia-ADHD
185 relationship, preeclampsia/SGA-ADHD (i.e SGA baby exposed to preeclampsia) relationship and
186 the relationship between preeclampsia without SGA and ADHD.

187 Similar to a previous ADHD study conducted on this population (and because a diagnosis of
188 ADHD is less likely to occur before this time)¹⁷, follow-up began from a child's third birthday, (or

189 1st January 1997 for children who turned three years of age before 1997). Children continued to
 190 be followed up until he/she received a diagnosis of ADHD, prescription for ADHD, death,
 191 emigration, or the study period had ended (31st December 2016).

192 Partially adjusted models were stratified for year of birth in order to satisfy the proportional hazard
 193 assumption (model 1). Fully adjusted models (model 2) controlled for year of birth, infant sex,
 194 maternal age, parental country of birth, parity, parental depression, bipolar disorder, and non-
 195 affective psychiatric disorder, family income, maternal smoking status, BMI at first antenatal visit,
 196 gestational weight gain and parental level of education.

197 *Sibling-matched analysis:* We conducted a sibling-matched analysis (model 3) to control for
 198 shared genetic and familial confounding, using stratified Cox regression. This analysis was
 199 matched on maternal ID and consisted of a separate stratum for each family in order to estimate
 200 the probability of ADHD within family²⁰. We adjusted for the same potential confounders as
 201 model 2 with the exception of maternal country of birth as this is the same across sibling pairs.
 202 Finally, we repeated these analyses, firstly, including only those with both an ICD code for ADHD
 203 and if the subject was in receipt of ADHD medication, and secondly, including only those with an
 204 ICD code for ADHD.

205 *Post-hoc analysis:* We examined the association between SGA only and ADHD compared to non-
 206 exposure to SGA/non-exposure to preeclampsia.

207 *E-value:* We calculated the E-value for the statistically significant primary effect estimates and
 208 lower limits of their 95% confidence interval (CI) to examine the extent of unmeasured
 209 confounding, using the publicly available online E-value calculator:
 210 (<https://evaluate.hmdc.harvard.edu/app/>)^{21, 22}. In summary, an E-value is a continuous measure that
 211 quantifies the minimum strength of association an unmeasured confounder would need to have
 212 with both preeclampsia and ADHD in order to explain away an effect estimate²².

213 *Sensitivity analyses:* We conducted several sensitivity analyses, decided *a priori*. For example,
 214 while classifying preeclampsia into mild/severe is not recommended in clinical practice because it
 215 is a complex disorder that can deteriorate rapidly, gestational age is sometimes used as a proxy for
 216 preeclampsia with severe features. As a result, preeclampsia could be considered severe if delivery
 217 occurred before 34 weeks' gestation²³. Therefore, we examined the association between
 218 preeclampsia and ADHD by gestational age. In addition, it is possible that a mother's lifestyle
 219 factors could change between pregnancies. As a result, we excluded women who had preeclampsia
 220 in her first pregnancy, and examined a preeclampsia-ADHD relationship in women who had a

221 diagnosis of preeclampsia in subsequent pregnancies only. Additional sensitivity analyses
222 included restricting the study population to 2001-2010 (when outpatient data on ADHD started to
223 become available), and restricting the study population to 1994-2010 to ensure every child begins
224 follow-up at their third birthday. Furthermore, we included 'preeclampsia excluding chronic
225 hypertension' as the exposure, and 'preeclampsia with chronic hypertension' as the exposure. We
226 examined preeclampsia-ADHD excluding those with a family history of mental illness. We
227 analysed the relationship between preeclampsia with low/intermediate APGAR score at five
228 minutes, while we also examined a preeclampsia-ADHD relationship by maternal age, in addition
229 to preeclampsia-ADHD by BMI group at time of first antenatal visit. Finally, we investigated a
230 preeclampsia-ADHD association by gender.

253 **Results**

254 **Descriptive Statistics**

255 A total of 2,142,694 live births were recorded in the Swedish Medical Birth Register between
256 1990 and 2010. After excluding 61,172 multiple births, 30,636 children who were censored before
257 their third birthday, and 3267 children who turned three years of age before 1997 but were
258 censored before follow-up began on 1st January 1997, a total of 2,047,619 children remained in
259 the final cohort (Table 1).

260 There were 57,493 (2.8%) children exposed to preeclampsia and 7191 (0.4%) exposed to
261 preeclampsia and SGA combined. There were 114,934 (5.6%) cases of ADHD. Of these 101,075
262 (87.9%) cases were prescribed ADHD medication at some point, and 94,708 (82.4%) cases had an
263 ICD diagnosis. A total of 80,849 (70.3%) cases were recorded with both an ICD code and
264 medication, while there were 13,859 (12.1%) cases with an ICD code only, and 20,226 (17.6%)
265 cases with medication only.

266

267 **Association between preeclampsia, preeclampsia/SGA and ADHD**

268 In the fully adjusted model (model 2), the results suggested an association between preeclampsia
269 and ADHD (HR: 1.15, 95% CI: 1.12, 1.19) compared to those unexposed to preeclampsia. Result
270 of the sibling-matched analysis (model 3) did not significantly change (HR: 1.13, 95% CI: 1.05,
271 1.22). The HR for those born SGA and exposed to preeclampsia was 1.43 (95% CI: 1.31, 1.55) in
272 the adjusted model (model 2), and 1.55 (95% CI: 1.28, 1.88) in the sibling-match model (model 3),
273 while the HR for those exposed to preeclampsia but not born SGA was 1.12 (95% CI: 1.08, 1.16)
274 in model 2, and 1.09 (95% CI: 1.01, 1.18) in model 3. Limiting the data to those with both an ICD
275 code and medication data did not materially change results, while including only those with an
276 ICD code for ADHD produced similar results (Table 2).

277 **Post-Hoc Analysis**

278 The adjusted HR for SGA only (i.e. SGA without preeclampsia) and ADHD was 1.32 (95% CI:
279 1.27, 1.37), while the HR in the sibling-matched analysis was 1.29 (95% CI: 1.19, 1.39) compared
280 to non-exposure to SGA/non-exposure to preeclampsia (Table 2).

281

282 **E-Values**

283 The E-values for significant primary effect estimates were 1.51 for preeclampsia, 2.47 for
284 preeclampsia with SGA and 1.40 for preeclampsia without SGA, while the E-values for

corresponding lower limits of their 95% CI were 1.28, 1.88 and 1.11 respectively. (see eTable 1 in Supplement for worked example on preeclampsia-ADHD).

Sensitivity Analyses

Preeclampsia and ADHD by gestational age

When we restricted analysis to children born ≥ 39 weeks' gestational age, the HR for a preeclampsia-ADHD relationship was 1.07 (95% CI: 1.02, 1.12). Among children born at 37-38 weeks', the HR in those exposed to preeclampsia was 1.20 (95% CI: 1.13, 1.28), while the HR among those not exposed to preeclampsia was 1.09 (95% CI: 1.08, 1.11), when compared to non-exposure to preeclampsia in those born ≥ 39 weeks' gestational age. Exposure to preeclampsia (among children born 34-36 weeks') was associated with a 24% increase in likelihood of ADHD (HR: 1.24, 95% CI: 1.14, 1.35), while those unexposed to preeclampsia had a 14% increased likelihood of ADHD among those born at a similar gestational age (HR: 1.14, 95% CI: 1.11, 1.18). Finally, the HR among those exposed to preeclampsia (born < 34 weeks' gestational age) was 1.74 (95% CI: 1.60, 1.91), while the HR among those not exposed to preeclampsia (born < 34 weeks' gestational age) was 1.49 (95% CI: 1.42, 1.96) when compared to non-exposure to preeclampsia among those born ≥ 39 weeks' gestational age (Table 3).

Additional sensitivity analyses

Results of additional sensitivity analyses are outlined in eResults and eTable 2 in the Supplement and were not materially different from the primary analysis. In sum, when we excluded women who had preeclampsia in their first pregnancy, the adjusted HR was 1.21. When we restricted the study population to 2001-2010 and 1994-2010, the HR was 1.21 and 1.14 respectively. The fully adjusted HR for preeclampsia (excluding chronic hypertension) and preeclampsia (with chronic hypertension) were 1.15 and 1.18 respectively. The HR for preeclampsia (excluding those with a family history of mental illness was 1.16. Preeclampsia (with low/intermediate APGAR at 5 minutes) increased the likelihood of ADHD by 13% when compared to non-exposure to preeclampsia in those with a low/intermediate APGAR score. Results of the subgroup analysis suggested that preeclampsia was significantly associated with ADHD at each category of maternal age and at each category of BMI at first antenatal visit. The HR for preeclampsia-ADHD in males was 1.18 compared to non-exposure to preeclampsia in males, while the HR for preeclampsia-ADHD in females was 1.10 compared to non-exposure to preeclampsia in females. Finally,

exposure to preeclampsia in males was associated with a 9% increase in likelihood of ADHD when compared to exposure to preeclampsia in females.

Discussion

The aim of this study was to examine the association between preeclampsia and preeclampsia/SGA and ADHD, using a large population-based cohort study. We have yielded three principal findings. First, after controlling for known potential confounding factors, preeclampsia was associated with a 15% increase in likelihood of ADHD when compared to non-exposure to preeclampsia. This finding was similar in the sibling-matched analysis suggesting that this apparent preeclampsia-ADHD relationship was not due to shared genetics or familial environment. This result is in line with the pooled estimate from a systematic review, which suggested that preeclampsia was associated with a 30% increase in odds of ADHD, with individual study estimates ranging from 1.19 to 1.50⁶.

Second, as SGA is associated with uteroplacental dysfunction²⁴, and due to recent guidelines put forward by ISSHP to include uteroplacental dysfunction in the definition of preeclampsia, we combined preeclampsia and SGA into a single exposure as a crude proxy for preeclampsia with placental dysfunction. Being an SGA baby and exposed to preeclampsia was associated with a 43% increase in likelihood of ADHD in the fully adjusted model, and a 55% increase in likelihood of ADHD in the sibling-matched analysis, when compared to non-exposure to preeclampsia or SGA. This may suggest that placental pathology may be a common factor increasing the likelihood of ADHD given the stronger association with preeclampsia/SGA than preeclampsia alone.

Third, while preeclampsia was associated with ADHD, independent of gestational age, the likelihood of ADHD increases with decreasing gestational age. For example, preeclampsia was associated with a 7% increase in likelihood of ADHD when we restricted the analysis to those born ≥ 39 weeks' gestation. However, the HR increases to 1.74 among those exposed to preeclampsia and born at < 34 weeks' gestation.

349

350 This apparent preeclampsia-ADHD association may lack specificity however, as preeclampsia is
351 associated with several neurodevelopmental outcomes such as autism spectrum disorder (ASD),
352 cognitive impairment and intellectual disability (ID) in previous literature⁶. Therefore,
353 preeclampsia could in fact be a risk factor for poor neurodevelopmental outcome in general, with
354 the specificity of outcome (e.g. ADHD, ASD, ID etc.) being determined by underlying genetic risk
355 factors²⁵.

356

357 **Potential Mechanisms**

358 The molecular basis of a preeclampsia-ADHD relationship remains unknown, and there are few
359 studies that address the potential biological mechanisms of ADHD specifically. Animal models
360 have shown that activation of interleukin-17a (IL-17a) in the fetal brain, in response to maternal
361 immune activation, is associated with behavioural disturbances and an abnormal cortical
362 phenotype in affected offspring^{26, 27}. Therefore, we can speculate that maternal inflammation may
363 be one such mechanism given the role of preeclampsia in chronic immune activation and elevated
364 levels of inflammatory cytokines such as IL-17a^{26, 28, 29}. In a separate study, maternal depressive
365 symptoms throughout pregnancy were shown to be associated with ADHD in offspring³⁰. As
366 prenatal depression is linked to an increase in levels of pro-inflammatory cytokines³¹, it is possible
367 that the inflammatory response observed in preeclampsia may have a similar inflammatory
368 mediated effect on ADHD-risk.

369 However, it may also be possible that lifestyle factors not available in the registers, such as
370 maternal alcohol consumption may also play a role. Alcohol consumption during pregnancy has
371 been shown to affect placentation, fetal growth, and likelihood of ADHD^{32, 33}. As preeclampsia is,
372 at least in part, a disease of placentation, leaving the fetus vulnerable to the effects of placental
373 pathology, particularly fetal growth restriction², it is plausible that maternal alcohol consumption
374 during pregnancy may contribute the observed preeclampsia-ADHD association.

375

376 **Strengths and Limitations**

377 There are several strengths in this study. To our knowledge, it is the largest epidemiological study
378 to examine the association between preeclampsia-ADHD to date. Use of National Registers
379 minimised recall bias, while also allowed us to control for a wide range of confounding factors. In
380 addition, the sibling-matched analysis allowed us to adjust for unmeasured confounding factors

381 shared by siblings such as family environment, diet, lifestyle factors, maternal characteristics, and
382 genetic factors¹⁴. Furthermore, use of the E-value allowed us to quantify Bradford-Hill's
383 consideration of 'strength of association' in an attempt to investigate the robustness of our effect
384 estimates to unmeasured confounding²².

385 However, this study also contains several limitations. First, sibling-matched analysis may have
386 reduced confounding due to shared genetic and familial factors. However, this method can only
387 adjust for factors that are constant between pregnancies³⁴ and the possibility of residual
388 confounding cannot be ruled out in observational studies. Taking preeclampsia-ADHD as an
389 example: (E-value for effect estimate = 1.51), an unmeasured confounder associated with both
390 preeclampsia and ADHD by a risk-ratio of 1.51 may potentially explain away our preeclampsia-
391 ADHD effect estimate of 1.13. However, the effect-estimate for preeclampsia/SGA combined is
392 less likely to be explained away by unmeasured confounding with an E-value of 2.47.
393 Nonetheless, we cannot dismiss the potential effect of factors such as maternal alcohol
394 consumption could have on findings. Second, a lack of robust data on gestational hypertension
395 limited our analysis to preeclampsia-ADHD only. Therefore, our comparison groups may contain
396 women with a diagnosis of gestational hypertension, and while previous literature suggests a
397 positive gestational hypertension-ADHD association³⁵, this would likely bias our results towards
398 to the null. Third, as outpatient data only started becoming available in 2001, more severe cases of
399 ADHD may have been overrepresented in our data. However, when we restricted the study
400 population to 2001-2010, results were not materially different from our main findings suggesting
401 that the inclusion of less severe cases after 2001 may not have had a large impact on findings.

402 In conclusion, this population-based cohort suggests that preeclampsia as well as
403 preeclampsia/SGA was associated with ADHD. Placental pathology may be a common
404 mechanism increasing the likelihood of ADHD given the stronger association with
405 preeclampsia/SGA, rather than preeclampsia alone. Further research is needed in order to clarify
406 this association, explore modifiable risk factors and identify those most-at-risk babies following
407 delivery.
